Role of microbes in vermicomposting:

Recycling organic wastes through Vermiculture Biotechnology (VBT) is being considered an economically viable solution. Earthworms are regarded as natural bioreactors which proliferate along with other microorganisms and provide required conditions for the biodegradation of wastes. Vermicomposting involves bio oxidation and stabilization of organic material through the interactions between earthworms and microorganisms.

Worms like to feed on slowly decomposing organic materials like fruit and vegetable scraps. Worms produce castings that contain beneficial microbes and nutrients, which makes a great soil amendment. Worms are very efficient at breaking down food scraps and can eat over half their body weight in organic matter every day. Vermicasting, also called vermicomposting, is the processing of organic wastes through earthworms . It is a natural, odourless, aerobic process, much different from traditional composting. Earthworms ingest waste, then excrete casts – dark, odourless, nutrient- and organically rich, soil mud granules that make an excellent soil conditioner.

- The composted product is safe and easy to handle, and does not induce nitrogen deficiency in recipient plants by nitrogen stabilization in the compost.
- It suppresses disease infestation by partial sterilization and detoxifies pollutants.
- Compost material is principally used for the reclamation of drastically disturbed. Example: mined soil, landscaping and agriculture.
- Compost finds unrestricted application in parks and gardens for ornamental plants, in land reclamation and highway beautification projects.
